Corresponding author:
Circulating tumor cells (CTCs) have demonstrated potential as a prognostic marker of metastatic development and therapeutic efficacy. However, the incurable metastasis can already be developed at the time of initial diagnosis with the existing CTC assays. Alternatively, tumor-associated particles (CTPs) including exosomes, can be a more valuable prognostic marker because they can be released from the primary tumor long before CTCs and in larger amount. However, little progress has been made in high sensitivity detection of CTPs, especially in vivo. We show here that in vivo integrated photoacoustic (PA) and fluorescence flow cytometry (PAFFC) can be used for detection of single CTPs at least in melanoma and breast cancer models using intrinsic melanin, dyes, and genetically modified cells with fluorescent proteins as PAFFC contrast agents. The two-beam, time-of-flight, PAFFC can also measure the sizes of CTPs, bulk and rolling CTCs, and CTC and CTP clusters producing narrow, medium, and wide signal peaks, respectively, with no influence of blood flow instability. This technique revealed a higher concentration of CTPs than CTCs at an early cancer stage. Because even single tumor cell can release many CTPs, and in vivo PAFFC can examine the whole blood volume, the proposed diagnostic platform has a potential for dramatic improvement (up to $10^5$ fold) the sensitivity of cancer diagnosis compared to CTC assays ex vivo.

1. Introduction

Most deaths from cancer (up to 90%) result from metastases for which there are no effective therapies [1-5]. Studies performed in ours and other laboratories have demonstrated the tremendous potential of circulating tumor cells (CTCs) as a prognostic marker of metastatic development and therapeutic efficacy [6-14]. Currently available advanced CTC assays (e.g. CellSearch and microfluidic CTC chips, among others) [10] have provided many biological discoveries that include high CTC heterogeneity, the presence of tumor-initiating and dormant cells, CTC epithelial–mesenchymal transition, and CTC-emboli with high metastatic activity. However, despite enormous efforts in the development of new CTC assays, the principle limitation of all existing technologies is the inherently low sensitivity of detection at around 1–10 CTCs/ml, which is primarily due to the sampling of a small blood volume (1-10 mL). As a result, the existing CTC assays can miss up to $10^3$-10^4 CTCs (i.e. 99.9% of CTCs) in the entire blood volume, one of which could easily drive metastatic progression to an incurable stage before CTCs can be detectable [10]. Because existing CTC assays cannot provide early enough cancer diagnosis, it is possible that it is too late to treat a patient at the time of initial testing.

In addition to CTCs, tumors secrete extracellular vesicles, which include exosomes and microparticles, which we will collectively refer to here as circulating tumor-associated particles (CTPs). Microparticles, including microvesicles (100 nm-1µm), bud directly from the plasma membrane. Whereas exosomes (30-300nm) have endosomal origins [42]. These CTPs can
harbor cancer cell signatures associated with local and metastatic progression (e.g. membrane proteins and microRNA) [15-32]. Because they can be released from the primary tumor long before CTCs and are vastly more abundant, CTPs have the potential to be a valuable prognostic tool. A single tumor cell may produce thousands of CTPs. Thus, unlike CTCs, CTPs can be present in plasma at very high concentrations (e.g. in some cases up to $10^{10-12}$ CTPs/mL vs. $1-10^5$ CTCs/mL) and could also be used as markers of non-metastatic cancers when no CTCs are present in blood. CTPs can also traffic between cellular populations to help create pre-metastatic niches [19].

However, little progress has been made in assessing the diagnostic value of CTPs because of the many challenges associated with their small sizes (30–300 nm and even larger), biological diversity (i.e. origins, structures, functions, biogenesis, and secretion mechanisms) and the limitation of detection methods [23-32]. For example, among different detection methods (e.g. RT-PCR, cytometry, Raman microspectroscopy, transmission electron microscopy [TEM]), Western blot and chemiluminescence ELISA have demonstrated the best detection limits of $10^5$ - $10^7$ CTPs (exosomes) in a few mL sample. A new nano-plasmonic sensor improved this limit to 3000 CTPs [29], which is still ~10$^3$-fold lower than the threshold for CTCs (~1 CTC/ml). In brief, there are no methods that currently exist for the selective detection and identification of CTPs in circulation in vivo. However, the recent advances in the development of multimode photoacoustic (PA)-fluorescence flow cytometry (PAFFC) [34-41] provided a unique diagnostic platform to detect and identify CTPs directly in the bloodstream. This platform opens the opportunity for the examination of nearly the entire volume of blood (up to 3-5 L). This allows for a dramatic increase in sample volume, and hence, chances to detect rare circulating disease-associated markers, compared to conventional blood tests involving blood samples of just few mL. A combination of CTC and CTP detection may dramatically (100–1000-fold) increase the sensitivity of in vivo flow cytometry due to a tumor’s potential ability to release up to 1000-fold more CTPs than CTCs. Here, we demonstrate the first proof of this concept using in vivo flow cytometry platform for detection of CTPs at early disease stages.

2. Materials and Methods

2.1. Photoacoustic (PA) and fluorescence flow cytometry (PAFC and FFC, respectively) platform.

Principles of PAFC and FFC as well as their integration (PAFFC) were described in detail elsewhere [33-41]. Briefly, one or several laser beam irradiates a circulating object directly in blood flow. This produces PA waves or fluorescence light (referred as PA and fluorescence signals), that are detected with an ultrasound transducer and photodetector, respectively (Fig.1A). Skin and many RBCs in the detection volume create constant background signals. To be detectable, individual targets (i.e. CTCs and CTPs) must have higher localized absorption and fluorescence than background signals. The integrated PAFFC setup was based on Nikon Eclipse E400 microscope platform (Nikon Instruments Inc., USA) with a high pulse repetition rate (10 kHz) nanosecond (0.6-8 ns) lasers operating at 532 nm and 820 nm (LUCE 532, Crystal and LUCE 820 [Bright Solutions], respectively) for PA detection of CTPs with intrinsic melanin or labeled with nanoparticles as PA contrast agents and a continuous wave (CW) 488 nm laser diode (Power Technologies, Alexander, AR) for fluorescence detection of CTPs expressing green fluorescence protein (GFP) or labeled with fluorescence tags. Laser beams were focused with shaping on sample into a 6 µm x 60 µm line using a cylindrical lens and 40× objective (Plan Fluor, NA 0.65; Nikon Instruments). The same objective collected fluorescence
from GFP or fluorescence labels. PA signals from circulating objects were detected by an ultrasound transducer (model 6528101, 3.5 MHz, 5.5 mm in diameter; Imasonic Inc., Besancon, France) and then amplified (amplifier model 5662B, 50kHz - 4 MHz; Panametrics). To collect signals, the setup was equipped with an analog-to-digital converter board (PCI-5124, National Instruments, Austin, TX) controlled using custom LabVIEW software. PA signals were sampled at 200M samples/s with 12-bit resolution. Fluorescence signals from a photomultiplier tube were sampled at a rate of 4 MHz and down-sampled to 10 kHz with 400 points on average. All the data was presented as signal traces in which amplitudes, shapes, and widths for each transient peak exceeding the background level were analyzed with customized software.

2.2. In vitro PAFFC analysis of CTCs and CTPs.

In vitro PAFFC was used to verify in vivo data because there is a higher sensitivity in vitro due to low light attenuation, autofluorescence, absorption background, well-controlled flow parameters, and sample dilution to exclude overlapping peaks from closely located objects. Specifically, in vitro analysis of CTPs and CTCs was performed in a 50 and 100 µm (i.d.) square quartz capillary in phosphate-buffered saline (PBS) or blood. The flow velocity of 1-5 mm/s was controlled with a syringe pump (Fig. 1B). To ensure that only one cell/particle is in the detection volume at a time, the solution of cells or particles were diluted properly. PA and fluorescence signals were detected through the capillary walls using the integrated PAFFC system as described above. PA and fluorescence traces were analyzed to identify a transient increase in PA or fluorescence signal amplitudes during a short time window (typically ~0.5 ms). The 2D scatter plots are constructed as PA signal amplitude vs fluorescence intensity with each object presented as a single dot.

2.3. In vivo flow cytometry using two-beam time-of-flight schematics.

The principle of the time-of-flight flow cytometry technique using preferentially one laser beam was reported previously [38-40]. Briefly, in a modified schematic, a CTP or CTC traverses two linear laser beams in the vessel (Fig. 1C) separated by a fixed distance (20-40 µm). During passing each laser beam the objects in flow produce a signal detected by the corresponding detector (Fig. 1D). Thus, the same object appears with a certain time shift on two data traces. Since the distance between the excitation laser beams is well established, the time shift in the data traces gives the exact cell velocity in flow. Secondly, the width of the cell signal (the time it takes for a cell to travel through a single laser beam) depends on the laser beam width, object velocity, and size. Thus, only an object’s size is unknown, as the laser beam width can be calibrated using objects of a known size (e.g. beads). The combination of these two approaches provides a full data set for each circulating object and this allows us to identify its size and velocity in flow. This mode can be applied to cells with intrinsic contrast agents (e.g. with melanin) or cells targeted by exogenous labels (e.g. nanoparticles). As CTPs have different structural and molecular composition depending on the cancer type and stage, the analysis of
width and shape of PA and fluorescence signals provide specific CTP’s size which is distinctive from CTC parameters.

D, Signal diagram for CTC and CTP identification in two-beam time-of-flight mode.

2.4. Cells.

Mouse melanoma (B16F10), human breast cancer (MDA-MB-231) and rat adenoarccinoma (MTLn3) cell lines expressing green fluorescent protein (GFP) and Dendra2, were employed to provide opportunities for the monitoring of CTCs and CTPs in vitro in PBS and in the xenograft of a nude mouse model (below). The cell lines were purchased from ATCC and were cultured in Dulbecco’s Modified Eagle Medium (DMEM) with high glucose (Gibco) +10% Fetal Bovine Serum (FBS) and penicillin-streptomycin. The MTLn3 adenocarcinoma cells expressing Dendra2 protein were maintained in a-minimum essential medium (Invitrogen/Life
Technologies) with 10% fetal bovine serum and penicillin-streptomycin (Invitrogen/Life Technologies). Viable cells were re-suspended in PBS to the desired concentration.

2.5. Nanoparticles.

Gold nanorods (GNRs) were from Nanopartz (Loveland, CO) with an absorption maximum at 820 nm (GNR-820). These nanoparticles follow the main requirements for targeting of CTCs and CTPs: small sizes (≤ 40-60 nm), low toxicity with polyethylene glycol-coating (PEG), high near infrared (NIR) absorption, and easily conjugated. Specifically, GNR-820 were conjugated with folic acid to target surface folate receptors expressed in breast cancer cells and not normal blood cells.

2.6. Animals.

Animals were used in accordance with a protocol approved by the University of Arkansas for Medical Sciences Institutional Animal Care and Use Committee. Nude mice (nu/nu), 8–10 weeks old, weighing 20–30 g, were procured from a commercial source for use in the experiments. The animals were anesthetized by isoflurane and placed on a heated microscope stage at 38 °C (body temperature). To create a primary tumor with metastatic dissemination, mice (n = 8) were inoculated with 1-3×10^6 Dendra2- MTLn3 cells in an ear. The mice were examined every other day with PAFFC to define the appearance of CTPs and CTCs.

Subcutaneous inoculation of 1x10^6 tumor cells (B16F10 and MDA-MB-231) provided the tumor model on the mouse's back. For in vivo monitoring of CTCs and CTPs, mice were anesthetized using isoflurane inhalation (1.2%). The mouse ear was spread over the stage glass window and measurements were performed in 40-60 µm ear veins. All experimental sessions consisted of continuous monitoring of CTCs and CTPs using the PAFFC system. In PAFC, the transducer was placed gently on the skin close to the laser beam with transparent ultrasound gel used for acoustic coupling. Mouse blood was collected from the tail vessel for in vitro testing using in vitro PAFFC and fluorescence microscopy. A total of five animals were used for each experiment unless otherwise noted.

2.7. Exosomes isolation and Western blotting.

B16F10 cells, purchased from ATCC, were cultured overnight in Dulbecco’s Modified Eagle Medium (DMEM) high glucose (Gibco) +10% Fetal Bovine Serum (FBS). Cells were then washed 3 times with 1X PBS and fresh serum free DMEM was added and the cells were incubated for a further 24 hours. The serum free medium was collected and exosomes were isolated through a series of ultracentrifugation steps. In brief, the collected media was subjected to the following centrifugation steps, 600g for 20 minutes and 10,000g for 30 minutes wherein the pellet was discarded and the supernatant was collected. Finally the supernatant was subjected to an ultracentrifugation step of 150,000g for 3 hours. After ultracentrifugation, the pellet formed was washed in PBS. After the final washing, the pellet was resuspended in PBS and used for further analysis. Similarly, exosomes were also isolated from mouse breast cancer cell line-4T1 and human glioma cell line-U87.

After harvesting media, the cells were lysed in RIPA buffer containing protease and phosphatase inhibitors. The total protein content of cell lysates and exosomes was determined using the BCA protein assay kit from Thermo Scientific. Equivalent quantities of cell lysates and exosomes were resolved onto SDS-PAGE gels and transferred to a PVDF membrane. The
PVDF blot was blocked with 5% non-fat milk in tris-buffered saline (TBS) containing 0.1% tween20. The blots were then probed with the primary polyclonal antibodies against CD63 (SBI Biosciences, Palo Alto, CA), or beta-actin (Abcam, Cambridge MA). The blots were then probed with horse radish peroxide (HRP) conjugated secondary antibodies (Santa-cruz Biotechnology, Dallas, TX) against the primary antibodies. The blots were then developed using a chemiluminescence reagent and blots detected using the BioRad Chemidoc MP system (Hercules, CA).

2.8. Statistical analysis.

Mouse was subjected to in vivo monitoring from 30 min up to 3 hours depending on the experimental task. To equalize the data changes due to vessel size, position of day-to-day tests, and mouse individuality, similar vessels in the mouse ear with diameters of 40-60 µm were used for monitoring a minimum of two times at different laser positions with similar vessel size. Results are expressed as means plus/minus the standard error of at least three independent experiments (P <0.05). MATLAB 7.0.1 (MathWorks) was used for the statistical calculations.

3. Results and Discussion

3.1. Detection of mimic CTPs in vitro and control mice.

Melanin in melanoma cells has been used previously by our laboratory as an intrinsic PA contrast agent for the detection of CTCs in vitro and in vivo in both animal models and cancer patients [34-35]. Based on this experience, we isolated exosomes from melanoma cells (B16F10) (Fig 2A, B) using well-established isolation procedures (Fig 2C) to verify the capability of the integrated PAFFC system to detect CTPs in vitro. TEM (Fig 2A and D) and dark field (Fig. 2B) imaging revealed exosomes with sizes in the range of 60-90 nm. Some portion of exosomes were relatively dark suggesting the presence of melanin. We also observed rare, larger exosome clusters with sizes up to ~1 µm. Further characterization of isolated exosomes was carried out using Western blot by probing for the exosomal marker protein CD63. CD63, a tetraspanin molecule, is highly enriched in exosomes in contrast to total cell lysate. The Western blots shows that compared to the cell lysates, CD63 was present in abundant quantities (Fig 2E) in the isolated exosomes and also in microvesicles. Beta-actin was used as a loading control to depict relative quantities of protein samples loaded onto SDS-PAGE gels. Exosomes and microvesicles isolated from B16F10 cells were stained with PKH26 fluorescent dye (lipid membrane stain) and analyzed using both PA and fluorescent flow cytometry modules (PAFC and FFC) in vitro in a 50-µm capillary flow tube. B16F10 exosome and microvesicle staining with the bright membrane fluorescence dye (PKH26) produced many fluorescence peaks (Fig. 3A,B) and coincident PA transient signals (Fig.3A,B) generated by 820 nm pulse laser in the spectral range with no dye absorption (dye absorbs in visible range only). Like conventional flow cytometry, the fluorescent-PA data was presented in 2-D scale (Fig.3C, D). The analysis of this data allowed us to identify three types of CTPs among microvesicles released from B16F10 cells: 1) non-pigmented CTPs (only fluorescence signals), 2) pigmented CTPs (both fluorescence and melanin-related PA signals, and 3) bare melanin particles (see below, Fig.3C, D). On average, the total number of pigmented CTPs was ~10%. However, more than 30% of CTPs containing melanin were also enveloped into a lipid bilayer like most of the exosomes. Such envelope may dramatically increase the diffusion rate for exosomes allowing them to easily penetrate into blood circulation and providing a natural source of early biomarkers for cancer diagnosis and monitoring.

Figure 3: PA and fluorescence detection of CTPs in flow in vitro and in vivo. In vitro fluorescence PA signal traces of PKH26 dye stained exosomes (A) and micro-vesicles (B) from
B16F10 melanoma cells in a 50 µm capillary tube. C, 2D analysis of exosome (C) and microvesicle (D) detection in Figs. 3A and 3B. E, In vivo PA detection of exosomes from B16F10 cells which were intravenously (i.v.) injected in a healthy control mouse. PAFC parameters: a high pulse repetition rate (10 kHz) nanosecond (0.6-8 ns) laser operating at 820 nm with an energy fluence of 30-50 mJ/cm².

Thus, some of the CTPs secreted from melanoma cells can be detected with PAFC in label-free mode. Indeed, intravenous injection of exosomes isolated from melanoma cells in control mice followed by the monitoring of microvesicles in the ear of a mouse with PAFFC led to the appearance of PA peaks (Fig. 3E). The clearance rate (lifetime) of these externally introduced particles (mimic CTPs) was around 10-15 min; however some signals appeared even after one hour during the continuous PA monitoring procedure. The number of PA signals and their amplitudes in vivo in the presence of background from skin and blood was lower compared to almost ideal optical condition in vitro (Fig. 3A,B). Obviously, the conditions associated with light attenuation in biological tissues and background noise limit the sensitivity of most optical methods in vivo. The advantage of the PAFFC platform and, especially the PAFC module is the potential to further improve the performance in vivo, in particular, by nonlinear amplification of PA signals from CTPs by the use of a picosecond laser which is optimal for the effective generation of PA signals from small absorbing targets like CTPs (acoustic confinement [34]) and by the use of an optimized acoustic detection system.

3.2. PA detection of real CTPs in vivo using tumor-bearing mouse models.

To test the capability of PAFC to target CTPs in preclinical condition, we used an orthotopic xenograft mouse model of melanoma and metastatic breast cancer. These models were characterized by the early production of blood CTCs with the high probability for the appearance of CTPs. Melanoma CTCs and CTPs were detected in label-free mode using intrinsic melanin as PA contrast agent, while breast cancer CTCs with GFP were molecularly targeted by GNR conjugated with folic acid [37]. As described in previous papers [34, 37], molecular targeting was optimized initially in vitro. In particular, for the detection of labeled breast cancer cells we used laser energies that were a little below the label-free detection thresholds for breast cancer cells in control samples. Labeling specificity was provided through the bio-conjugation of GNR820 with folic acid for targeting of the surface folate receptors, which are highly expressed in breast cancer cells, but almost absent in normal blood cells. We explored the dependence of labeling efficiency from nanoparticle concentration. Breast cancer cells were labeled by GNR820-folic acid at concentrations ranging from 500 to 10,000 nanoparticles per one cell. Surprisingly, even 500 GNR conjugates per one cell was enough for effective PA detection of 30-40 % cells in vitro. At 2000-3000 GNRs per one cell, the cells provided detectable PA signals in blood backgrounds. Labeling in vivo was performed by intravenous injection (i.v.) injection of GNR solution (100 µl, ~10¹² GNRs/ml) into mouse blood circulatory system. Immediately after injection we observed the appearance of PA signals from GNR alone, mostly from their aggregates. Then, the PA signals quickly disappeared during ~5 minutes due to rapid clearance of GNR aggregates and appearance again PA signals from labeled cells after 20-30 minute [34].

We observed PA signals with narrow, medium and wide widths associated with CTPs, CTC and CTC aggregates, respectively (Fig. 4A, B). Surprisingly, the amplitudes of PA signals from CTPs were only a little lower (3-5 times) than those from CTCs, which suggests a highly localized concentration of PA contrast agents in CTPs (e.g., melanin and GNRs). Image
analysis of collected mouse blood confirmed *in vitro* the presence of CTCs and CTPs (Fig. 4C, D).

The travel time of a CTC with a typical diameter ($d_{\text{CTC}}$) of 12–25 µm through the 3–5-µm-wide one laser beam spot ($d_{\text{B}}$) determines the duration of a signal ($\Delta t$) through the simple relation: $\Delta t = (d_{\text{CTC}} + d_{\text{B}})/V_F$ (3–6 ms), where $V_F$ is the flow velocity (3–7 mm/s in a mouse ear vessel). Thus, CTC (and CTP) size can be found if $d_{\text{B}}$ and $V_F$ are known [34, 38, 40] Usually, $V_F$ is not precisely known. Thus, in figure 4A, B we can definitely operate with the widths of CTPs and CTCs and with some precaution of their size estimation using single laser beam.

Insets show typical peak shapes for CTCs and CTPs. **B**, PA signal traces for breast cancer model using MDA-MB-231 cells labeled with conjugated gold nanoparticles. Insets show typical narrow peaks from CTPs and wider peaks from CTCs and/or CTP clusters. **C, D** Images of CTPs in blood collected from melanoma (**C**), and carcinoma (**D**) tumor-bearing mice using cells with GFP.

3.3. *Analysis of CTC and CTC sizes using in vivo two-beam flight—of flight flow cytometry.*
As mentioned in previous sub-section, time-of-flight data without the exact information on linear cell velocity cannot be used if the some changes in a biological system over an extended period of time. This issue was explored using MTLn3 adenocarcinoma cell line expressing Dendra2 fluorescein protein and FFC module of PAFFC. Figure 5A shows, how difficult to estimate the absolute cell size even for a uniform cell population with much less probability to identify small CTPs. Increase in blood flow velocity (Fig. 5A, inset) decrease time-of-flight and introduce an error into an estimated cell size. To overcome this problem, we explored two-beam beam schematic (Fig. 1C) with which we can measure the delay between the two signal peaks (ΔT) created as a CTC or CTP sequentially crosses the two beams (Fig.1D). This enables calculating cell (object) velocity (\(V_o = L/\Delta T\)) and thus increases the accuracy of cell-size measurements (e.g., without the use of calibrated cell phantoms). For a cell producing signals on both channels (Fig. 5B), as mentioned above cell velocity can be calculated using only delay between signals (experimental data), the distance between the laser beams, \(L\) (constant hardware parameter). Indeed, our data indicated that in the same vessels there could be as slow cells, having large time-of-flight signal duration (\(\Delta T\) as FWHM of the peak) and long interval between red and green peaks in the data recording, so as fast cells with narrow peaks being close to each other. Thus, from the cell (object) velocity, \(V_o\), and time-of-flight data, FWHM, one can calculate cell (object) size as: \(D_{cell} = 2 \times \text{FWHM} / V_{cell}\), here a factor of 2 is used to calculate cell diameter.

In this case cell size data does not depend on flow velocity (Fig. 5C). We performed analysis of cell size distribution by injecting two-color fluorescent cells into blood circulation and monitoring transient signals using FFC. The acquired cells histogram data shows presence of individual cells in flow and of few aggregates (Fig.5D). The average cell size measured in vivo (14±1.4 µm) using only a-priori acquired data on beams separation and laser beam width correlated well with the \textit{in vitro} data on cell size for the same batch of cell: 12.8±0.26 µm acquired using transmission microscopy in a slide. Our data indicate that some signals may be attributed to fluorescent micro-particles or cell fragments having size of just a few micrometers.

Arrows indicate FWHM and $\Delta t$ delay parameters acquired for each cell. C, Cell size calculated from time-of-flight and cell velocity data. D, Cell size distribution histogram calculated from in vivo data.

3.4. Monitoring of CTPs at early cancer stages.

In order to develop an early cancer diagnosis tool based on the quantification of CTPs, it is important to confirm the original hypothesis that small tumor-associated particles appear earlier than CTCs in circulation and in much higher numbers due to a higher diffusion rate through healthy vasculature (early disease stage) than full-sized tumor cells. Two-color PAFFC operating in time-of-flight mode provides a unique opportunity to not only quantify CTP and CTCs in blood circulation, but to also assess the size of circulating particles (Fig. 6A,B,C right). A mouse model featuring Dendra2- MTLn3 cells implanted into mouse ear was used in this study. These cells were expressing switchable Dendra2 protein and provided two-color fluorescence in green and orange channels of the PAFFC system. The two-color time-of-flight PAFFC mode was used for both detection and size analysis of the circulating cells and cell fragments. Figure 6A, B, &C (left) demonstrates that the number of CTPs was substantially higher for the early stage of cancer development (day 5). At day 15th the relative number of signals from cells (9-18 µm) was higher than of CTPs, and by Day 25 a number of cell clusters have appeared in circulation. It should be noted that the actual number of CTPs can be much higher than the numbers detected here, as smaller cells and cell fragments have much lower fluorescence and it is much more difficult to detect such particles. Ex vivo analysis (similar to data in Fig. 4C, D) revealed many exosomes with sizes in the range of 100-300 nm.

4. Conclusions

Detection and identification of CTPs, especially at an early disease stage, is still challenging because of their small size, heterogeneity, as well as the limited sensitivity and specificity of analytical methods. Our first-of-their-kind results demonstrate the high potential for in vivo multicolor PAFFC platform that integrates PA and fluorescence methods to detect CTPs. To verify the detection of CTPs, we have used the coincidence of PA and fluorescence signals (Fig. 3A, B) using CTPs expressing melanin and labeled with PKH26 fluorescent membrane dye as PA and fluorescence reference signals. This integrated (PAFC +FFC) technique can be considered a unique research tool that uses animal models to provide insight into the role of CTPs in cancer staging and prognosis, while PAFC has the potential for future clinical applications, especially in label-free noninvasive mode for the detection of melanoma. The focus of this paper is on the detection of CTPs in vitro and in vivo in animal models using intrinsic melanin, dyes, and genetically modified cells with fluorescent proteins as PAFFC contrast agents. Certainly, fluorescent proteins may enhance the preclinical research of CTPs, however, the use of such proteins is difficult in patients, if not impossible. In future experiments, we hope to use molecular targeting such as tumor specific antibodies and engineered nanoparticles to distinguish tumor-associated exosomes from host exosomes. Targeting CTPs using engineered nanoparticles is a good alternative, but requires the reliable elimination of non-specific interactions and has toxicity concerns.

In our current studies in tumor-bearing mouse models, we were able to distinguish CTPs with narrower peak widths and smaller amplitudes, and single CTC or CTC aggregates with complex shapes and larger peak widths, using advanced PAFFC diagnostic platform (Fig. 4A-C). Using PA detection of circulating B16F10 mouse melanoma cells in label-free mode and detection of labelled MDA-MB-231 breast cancer cells, we observed a dramatic difference in time it takes cells to cross the irradiated blood volume. The typical transition time for CTCs was 2-4 ms, while some signals appeared for only a short time of 0.1-0.5 ms. This indicates that small sized CTPs are present in flow. We also discovered that CTPs appeared at early stages of cancer progression and in larger numbers than CTCs (Fig. 6E-F). While the hypothesis that CTPs are shed from a primary tumor before CTCs has not be shown in the clinic yet, our findings support this link between CTPs and CTCs. Based on the obtained data, we suggest that CTPs can be valuable tools in cancer staging, prognosis and to determine aggressiveness of the disease.

As mentioned, we cannot exclude aggregation (clumping) of CTCs and CTPs as well as the interaction of CTCs and potentially of CTPs with platelets. In particular, we have already observed CTC aggregates providing positive PA signals with some peaks having a broader width compared to single CTCs (e.g., ref. [34] and Figure 4A, B in the current manuscript). We have also developed negative contrast PAFC agents, in which the platelet clumps or so called white clots consisting of low absorbing platelets, fibrin, or white blood cells produce negative PA transient peaks in relatively strongly absorbing red blood cell (RBC) background (34-35). Moreover, using this mode we observed CTC-platelet clumps providing a complex of positive-negative peaks [34]. Thus, our techniques can potentially monitor the clumping of pigmented CTP with platelets leading to positive-negative PA peaks.

The safety of PAFC diagnostic platform using relatively low laser energy fluence were verified in our previous publications and summarized in this review [34]. In our current study, we used similar laser parameters (e.g., 30-50 mJ/cm²) and thus we do not expect laser-induced
CTC and CTP exosome photo-damage. Nevertheless, the safety issue will be carefully examined in our future studies.

Label-free detection of CTPs is possible for at least one cancer type, melanoma, which could be an optimal model to explore the clinical potential of PAFC. We would like to emphasize that for the first time, we have proposed a way to accurately measure the size of CTPs in vivo through the time-of-flight detection of CTPs between two laser beams (previously we and other laboratories estimated relative CTC sizes with the use of only one single beam) [38].

Hypothetically, our diagnostic platform can enhance the sensitivity of cancer diagnosis up to 10^6-fold compared to that of existing in vitro CTC assays through the synergy of the increased volume of blood that can be examined with the in vivo PAFC platform (~10^3 times) and the amplification of cancer markers in blood as a result of the potential for a single tumor cell to release many CTPs (~10^3 times). The limitations of our first-generation in vivo PAFC platform include the low sensitivity for small targets, and size controlling ≥0.5-1 µm due to non-optimized software which both did not allow us to achieve this dramatic potential improvement. On average, the percentage of detected pigmented exosomes was in the range of ~5%. Nevertheless, dramatically increased sensitivity may compensate for the missing or low pigmented cells. Moreover, more than 30% of CTPs that contained melanin also were enveloped into a lipid bilayer like most of the exosomes. Such envelope may dramatically increase the diffusion rate for exosomes which would allow them to easily penetrate into blood circulation and provide a natural source of early biomarkers for cancer diagnosis. We are confident that the sensitivity and specificity for detecting and identifying CTPs in blood can be significantly enhanced by the use of an advanced in vivo PAFFC-based platform that integrates high-pulse-repetition-rate picosecond lasers, a two-beam time-of-flight schematic, and multicolor plasmonic probes.
